12: Support Vector Machines (SVMs)

## <u>Support Vector Machine (SVM) - Optimization objective</u>

- So far, we've seen a range of different algorithms
  - With supervised learning algorithms - performance is pretty similar
    - What matters more often is;
      - The amount of training data
      - Skill of applying algorithms
- One final supervised learning algorithm that is widely used - **support vector machine (SVM)**
  - Compared to both logistic regression and neural networks, a SVM sometimes gives a cleaner way of learning non-linear functions
  - Later in the course we'll do a survey of different supervised learning algorithms
An alternative view of logistic regression

- Start with logistic regression, see how we can modify it to get the SVM
  - As before, the logistic regression hypothesis is as follows

$$h_\theta(x) = \frac{1}{1 + e^{-\theta^T x}}$$

  - And the sigmoid activation function looks like this

$$h_\theta(x) = g(z)$$

$$z = \theta^T x$$
  - In order to explain the math, we use z as defined above
- What do we want logistic regression to do?
  - We have an example where y = 1
    - Then we hope $h_\theta(x)$ is close to 1
    - With $h_\theta(x)$ close to 1, ($\theta^T x$) must be **much larger** than 0

  - Similarly, when y = 0

- Then we hope $h_\theta(x)$ is close to 0
    - With $h_\theta(x)$ close to 0, $(\theta^T x)$ must be **much less** than 0
  - This is our classic view of logistic regression
    - Let's consider another way of thinking about the problem
- Alternative view of logistic regression
  - If you look at cost function, each example contributes a term like the one below to the overall cost function

$$-(y \log h_\theta(x) + (1-y) \log(1 - h_\theta(x)))$$

    - For the overall cost function, we sum over all the training examples using the above function, and have a 1/m term
- If you then plug in the hypothesis definition ($h_\theta(x)$), you get an expanded cost function equation;

$$= -y \log \frac{1}{1 + e^{-\theta^T x}} - (1-y) \log(1 - \frac{1}{1 + e^{-\theta^T x}})$$

  - So each training example contributes that term to the cost function for logistic regression

- If y = 1 then only the first term in the objective matters
  - If we plot the functions vs. z we get the following graph
    - This plot shows the cost contribution of an example when y = 1 given z
      - So if z is big, the cost is low - this is good!
      - But if z is 0 or negative the cost contribution is high
      - This is why, when logistic regression sees a positive example, it tries to set $\theta^T x$ to be a very large term
- If y = 0 then only the second term matters
 - We can again plot it and get a similar graph
    - Same deal, if z is small then the cost is low
      - But if s is large then the cost is massive

SVM cost functions from logistic regression cost functions

- To build a SVM we must redefine our cost functions

- ○ When y = 1
  - ▪ Take the y = 1 function and create a new cost function
  - ▪ Instead of a curved line create two straight lines (magenta) which acts as an approximation to the logistic regression y = 1 function

$$-\log \frac{1}{1 + e^{-z}}$$
  - ▪ Take point (1) on the z axis
    - ▪ Flat from 1 onwards
    - ▪ Grows when we reach 1 or a lower number
  - ▪ This means we have two straight lines
    - ▪ Flat when cost is 0
    - ▪ Straight growing line after 1
  - ▪ So this is the new y=1 cost function
    - ▪ Gives the SVM a computational advantage and an easier optimization problem
    - ▪ We call this function **cost$_1$(z)**

- Similarly
  - ○ When y = 0
    - ▪ Do the equivalent with the y=0 function plot

$$-\log(1 - \frac{1}{1 + e^{-z}})$$
    - ▪ We call this function **cost$_0$(z)**
- So here we define the two cost function terms for our SVM graphically
  - ○ How do we implement this?

The complete SVM cost function

- As a comparison/reminder we have logistic regression below

$$\min_{\theta} \frac{1}{m} \left[\sum_{i=1}^{m} y^{(i)} \left(-\log h_\theta(x^{(i)}) \right) + (1 - y^{(i)}) \left((-\log(1 - h_\theta(x^{(i)}))) \right) \right] + \frac{\lambda}{2m} \sum_{j=1}^{n} \theta_j^2$$

  - ○ If this looks unfamiliar its because we previously had the - sign outside the expression
- For the SVM we take our two logistic regression y=1 and y=0 terms described previously and replace with
  - ○ cost$_1$(θ^Tx)
  - ○ cost$_0$(θ^Tx)
- So we get

$$\min_{\theta} \frac{1}{m} \sum_{i=1}^{m} \left[y^{(i)} cost_1(\theta^T x^{(i)}) + (1 - y^{(i)})cost_0(\theta^T x^{(i)}) \right] + \frac{\lambda}{2m} \sum_{i=1}^{n} \theta_j^2$$

SVM notation is slightly different

- In convention with SVM notation we rename a few things here
- 1) Get rid of the 1/m terms
  - This is just a slightly different convention
  - By removing 1/m we should get the same optimal values for
    - 1/m is a constant, so should get same optimization
    - e.g. say you have a minimization problem which minimizes to u = 5
      - If your cost function * by a constant, you still generates the minimal value
      - That minimal value is different, but that's irrelevant
- 2) For logistic regression we had two terms;
  - Training data set term (i.e. that we sum over m) = **A**
  - Regularization term (i.e. that we sum over n) = **B**
    - So we could describe it as A + λB
    - Need some way to deal with the trade-off between regularization and data set terms
    - Set different values for λ to parametrize this trade-off
  - Instead of parameterization this as A + λB
    - For SVMs the convention is to use a different parameter called C
    - So do CA + B
    - If C were equal to 1/λ then the two functions (CA + B and A + λB) would give the same value
- So, our overall equation is

$$\min_{\theta} C \sum_{i=1}^{m} \left[y^{(i)} cost_1(\theta^T x^{(i)}) + (1 - y^{(i)})cost_0(\theta^T x^{(i)}) \right] + \frac{1}{2} \sum_{i=1}^{n} \theta_j^2$$

- Unlike logistic, $h_\theta(x)$ doesn't give us a probability, but instead we get a direct prediction of 1 or 0
  - So if $\theta^T x$ is equal to or greater than 0 --> $h_\theta(x)$ = 1
  - Else --> $h_\theta(x)$ = 0

Large margin intuition

- Sometimes people refer to SVM as **large margin classifiers**
  - We'll consider what that means and what an SVM hypothesis looks like
  - The SVM cost function is as above, and we've drawn out the cost terms below
If $y = 1$, we want $\theta^T x \geq 1$ (not just ≥ 0)
If $y = 0$, we want $\theta^T x \leq -1$ (not just < 0)

  - Left is $cost_1$ and right is $cost_0$
  - What does it take to make terms small
    - If y =1
      - $cost_1(z)$ = 0 only when z >= 1
    - If y = 0
      - $cost_0(z)$ = 0 only when z <= -1
 - Interesting property of SVM

- - - If you have a positive example, you only really *need* z to be greater or equal to 0
      - If this is the case then you predict 1
    - SVM wants a bit more than that - doesn't want to *just* get it right, but have the value be quite a bit bigger than zero
      - Throws in an extra safety margin factor
- Logistic regression does something similar
- What are the consequences of this?
  - Consider a case where we set C to be huge
    - C = 100,000
    - So considering we're minimizing CA + B
      - If C is huge we're going to pick an A value so that A is equal to zero
      - What is the optimization problem here - how do we make A = 0?
    - Making A = 0
      - If y = 1
        - Then to make our "A" term 0 need to find a value of θ so (θ^T x) is greater than or equal to 1
      - Similarly, if y = 0
        - Then we want to make "A" = 0 then we need to find a value of θ so (θ^T x) is equal to or less than -1
    - So - if we think of our optimization problem a way to ensure that this first "A" term is equal to 0, we re-factor our optimization problem into just minimizing the "B" (regularization) term, because
      - When A = 0 --> A*C = 0
    - So we're minimizing B, under the constraints shown below

$$\min \frac{1}{2} \sum_{i=1}^{n} \theta_j^2$$

$$s.t. \quad \theta^T x^{(i)} \geq 1 \quad if \quad y^{(i)} = 1$$

$$\theta^T x^{(i)} \leq -1 \quad if \quad y^{(i)} = 0$$

  - Turns out when you solve this problem you get interesting decision boundaries

  - The green and magenta lines are functional decision boundaries which could be chosen by logistic regression
    - But they probably don't generalize too well
  - The black line, by contrast is the the chosen by the SVM because of this safety net imposed by the optimization graph
    - More robust separator
  - Mathematically, that black line has a larger minimum distance (margin) from any of the training examples
- o   By separating with the largest margin you incorporate robustness into your decision making process
- We looked at this at when C is very large
  - o SVM is more sophisticated than the large margin might look
    - ▪ If you were just using large margin then SVM would be very sensitive to outliers
  - ▪ You would risk making a ridiculous hugely impact your classification boundary
    - ▪ A single example might not represent a good reason to change an algorithm
    - ▪ If C is very large then we *do* use this quite naive maximize the margin approach
  - ▪ So we'd change the black to the magenta
  - ▪ But if C is reasonably small, or a not too large, then you stick with the black decision boundary
  - o What about non-linearly separable data?
    - ▪ Then SVM still does the right thing if you use a normal size C
    - ▪ So the idea of SVM being a large margin classifier is only really relevant when you have no outliers and you can easily linearly separable data
 - o Means we ignore a few outliers

Large margin classification mathematics (optional)
Vector inner products

- Have two (2D) vectors u and v - what is the inner product ($u^T v$)?

$$u = \begin{bmatrix} u_1 \\ u_2 \end{bmatrix} \quad v = \begin{bmatrix} v_1 \\ v_2 \end{bmatrix}$$

  - Plot u on graph
    - i.e u_1 vs. u_2

  - One property which is good to have is the **norm** of a vector
    - Written as ||u||
      - This is the euclidean length of vector u
    - So ||u|| = SQRT($u_1^2 + u_2^2$) = real number
      - i.e. length of the arrow above
      - Can show via Pythagoras
  - For the inner product, take v and orthogonally project down onto u
    - First we can plot v on the same axis in the same way (v_1 vs v_1)
    - Measure the length/magnitude of the projection

    - So here, the green line is the projection
      - p = length along u to the intersection
      - p is the magnitude of the projection of vector v onto vector u
  - Possible to show that
    - $u^T v = p * ||u||$
      - So this is one way to compute the inner product
    - $u^T v = u_1 v_1 + u_2 v_2$
    - So therefore
      - **p * ||u|| = $u_1 v_1 + u_2 v_2$**
      - This is an important rule in linear algebra
    - We can reverse this too
      - So we could do
        - $v^T u = v_1 u_1 + v_2 u_2$
        - Which would obviously give you the same number
  - p can be negative if the angle between them is 90 degrees or more
- - - So here p is negative
- Use the vector inner product theory to try and understand SVMs a little better

SVM decision boundary

$$\min_\theta \frac{1}{2} \sum_{j=1}^{n} \theta_j^2$$

$$\text{s.t.} \quad \theta^T x^{(i)} \geq 1 \quad \text{if } y^{(i)} = 1$$

$$\theta^T x^{(i)} \leq -1 \quad \text{if } y^{(i)} = 0$$

- For the following explanation - two simplification
  - Set $\theta_0 = 0$ (i.e. ignore intercept terms)
  - Set n = 2 - (x_1, x_2)
    - i.e. each example has only 2 features
- Given we only have two parameters we can simplify our function to

$$\frac{1}{2}\left(\theta_1^2 + \theta_2^2\right)$$

- And, can be re-written as

$$\frac{1}{2}\left(\sqrt{\theta_1^2 + \theta_2^2}\right)^2$$

  - Should give same thing
- We may notice that

$$\frac{1}{2}\left(\underline{\sqrt{\theta_1^2 + \theta_2^2}}\right)^2$$

$$= \|\theta\|$$

  - The term in red is the norm of θ
    - If we take θ as a 2x1 vector
    - If we assume $\theta_0 = 0$ its still true
- So, finally, this means our optimization function can be re-defined as

$$= \frac{1}{2}\|\theta\|^2$$

- So the SVM is minimizing the squared norm

- Given this, what are the $(\theta^T x)$ parameters doing?
  - Given θ and given example x what is this equal to
    - We can look at this in a comparable manner to how we just looked at u and v
 - Say we have a single positive training example (red cross below)
- o Although we haven't been thinking about examples as vectors it can be described as such
- o Now, say we have our parameter vector θ and we plot that on the same axis
- o The next question is what is the inner product of these two vectors

- ■ p, is in fact p^i, because it's the length of p for example i
    - ■ Given our previous discussion we know

$$(\theta^T x^i) = p^i * ||\theta||$$
$$= \theta_1 x^i_1 + \theta_2 x^i_2$$

    - ■ So these are both equally valid ways of computing $\theta^T x^i$
- What does this mean?
    - o The constraints we defined earlier
   - ■ $(\theta^T x) >= 1$ if $y = 1$

- (θ^T x) <= -1 if y = 0
  - Can be replaced/substituted with the constraints
    - p^i * $||\theta||$ >= 1 if y = 1
    - p^i * $||\theta||$ <= -1 if y = 0
  - Writing that into our optimization objective

$$\min_{\theta} \frac{1}{2} \sum_{j=1}^{n} \theta_j^2 = \frac{1}{2} \|\theta\|^2$$

$$\text{s.t.} \quad p^{(i)} \cdot \|\theta\| \geq 1 \quad \text{if } y^{(i)} = 1$$

$$p^{(i)} \cdot \|\theta\| \leq -1 \quad \text{if } y^{(i)} = 1$$

- So, given we've redefined these functions let us now consider the training example below

  - Given this data, what boundary will the SVM choose? Note that we're still assuming θ_0 = 0, which means the boundary has to pass through the origin (0,0)
    - Green line - small margins

      - SVM would not chose this line
        - Decision boundary comes very close to examples
        - Lets discuss *why* the SVM would **not** chose this decision boundary
  - Looking at this line
    - We can show that θ is at 90 degrees to the decision boundary
      - **θ is always at 90 degrees to the decision boundary** (can show with linear algebra, although we're not going to!)
- So now lets look at what this implies for the optimization objective
  - Look at first example (x^1)
- Project a line from x^1 on to to the θ vector (so it hits at 90 degrees)
  - The distance between the intersection and the origin is (**p^1**)
- Similarly, look at second example (x^2)
  - Project a line from x^2 into to the θ vector
  - This is the magenta line, which will be **negative** (**p^2**)
- If we overview these two lines below we see a graphical representation of what's going on;
- We find that both these p values are going to be pretty small
- If we look back at our optimization objective
  - We know we need p^1 * $||θ||$ to be bigger than or equal to 1 for positive examples
    - If p is small
      - Means that $||θ||$ must be pretty large
  - Similarly, for negative examples we need p^2 * $||θ||$ to be smaller than or equal to -1
    - We saw in this example p^2 is a small negative number
      - So $||θ||$ must be a large number
- Why is this a problem?
  - The optimization objective is trying to find a set of parameters where the norm of theta is small
    - So this doesn't seem like a good direction for the parameter vector (because as p values get smaller $||θ||$ must get larger to compensate)
      - So we should make p values larger which allows $||θ||$ to become smaller
- So lets chose a different boundary
- Now if you look at the projection of the examples to θ we find that p^1 becomes large and $||θ||$ can become small
- So with some values drawn in
- This means that by choosing this second decision boundary we can make $||\theta||$ smaller
    - Which is why the SVM choses this hypothesis as better
    - This is how we generate the large margin effect

- The magnitude of this margin is a function of the p values
    - So by maximizing these p values we minimize $||\theta||$
- Finally, we did this derivation assuming $\theta_0 = 0$,
    - If this is the case we're entertaining only decision boundaries which pass through (0,0)
    - If you allow θ_0 to be other values then this simply means you can have decision boundaries which cross through the x and y values at points other than (0,0)
    - Can show with basically same logic that this works, and even when θ_0 is non-zero when you have optimization objective described above (when C is very large) that the SVM is looking for a large margin separator between the classes

Kernels - 1: Adapting SVM to non-linear classifiers

- What are kernels and how do we use them
    - We have a training set
    - We want to find a non-linear boundary
- Come up with a complex set of polynomial features to fit the data
    - Have $h_\theta(x)$ which
        - Returns 1 if the combined weighted sum of vectors (weighted by the parameter vector) is less than or equal to 0

- Else return 0
  - Another way of writing this (new notation) is
    - That a hypothesis computes a decision boundary by taking the sum of the parameter vector multiplied by a **new feature vector f**, which simply contains the various high order x terms
    - e.g.
      - $h_\theta(x) = \theta_0 + \theta_1 f_1 + \theta_2 f_2 + \theta_3 f_3$
        - Where
          - $f_1 = x_1$
          - $f_2 = x_1 x_2$
          - $f_3 = ...$
          - i.e. not specific values, but each of the terms from your complex polynomial function
  - Is there a better choice of feature f than the high order polynomials?
    - As we saw with computer imaging, high order polynomials become computationally expensive
- New features
  - Define three features in this example (ignore x_0)
  - Have a graph of x_1 vs. x_2 (don't plot the values, just define the space)
  - Pick three points in that space
  - These points l^1, l^2, and l^3, were chosen manually and are called **landmarks**
    - Given x, define f1 as the similarity between (x, l^1)
      - $= \exp(- (|| x - l^1 ||^2) / 2\sigma^2)$
      $$\exp\left(-\frac{||x - l^{(1)}||^2}{2\sigma^2}\right)$$
      $=$
      - $|| x - l^1 ||$ is the euclidean distance between the point x and the landmark l^1 squared
        - Disussed more later
      - If we remember our statistics, we know that
        - σ is the **standard deviation**
        - σ^2 is commonly called the **variance**
    - Remember, that as discussed
    $$||x - l^{(1)}||^2 = \sum_{j=1}^{n} (x_j - l_j^{(1)})^2$$
  - So, f2 is defined as
    - $f2 = similarity(x, l^1) = \exp(- (|| x - l^2 ||^2) / 2\sigma^2)$
  - And similarly
    - $f3 = similarity(x, l^2) = \exp(- (|| x - l^1 ||^2) / 2\sigma^2)$
  - This similarity function is called a **kernel**
    - This function is a **Gaussian Kernel**
  - So, instead of writing similarity between x and l we might write
    - $f1 = k(x, l^1)$

Diving deeper into the kernel

- So lets see what these kernels do and why the functions defined make sense
  - Say x is close to a landmark
   - Then the squared distance will be ~0
      - So

$$f_1 \approx \exp\left(-\frac{0^2}{2\sigma^2}\right)$$

      - Which is basically e^{-0}
        - Which is close to 1
    - Say x is far from a landmark
      - Then the squared distance is big
        - Gives $e^{-\text{large number}}$
          - Which is close to zero
    - Each landmark defines a new features
- If we plot f1 vs the kernel function we get a plot like this
  - Notice that when x = [3,5] then f1 = 1
  - As x moves away from [3,5] then the feature takes on values close to zero
  - So this measures how close x is to this landmark
What does σ do?

- σ^2 is a parameter of the Gaussian kernel
  - Defines the steepness of the rise around the landmark
- Above example $\sigma^2 = 1$
- Below $\sigma^2 = 0.5$
  - We see here that as you move away from 3,5 the feature f1 falls to zero much more rapidly
- The inverse can be seen if $\sigma^2 = 3$
- Given this definition, what kinds of hypotheses can we learn?
  - With training examples x we predict "1" when
  - $\theta_0 + \theta_1 f_1 + \theta_2 f_2 + \theta_3 f_3 >= 0$

- For our example, lets say we've already run an algorithm and got the
    - θ_0 = -0.5
    - θ_1 = 1
    - θ_2 = 1
    - θ_3 = 0
  - Given our placement of three examples, what happens if we evaluate an example at the **magenta dot** below?

  - Looking at our formula, we know f1 will be close to 1, but f2 and f3 will be close to 0
    - So if we look at the formula we have
      - $\theta_0 + \theta_1 f_1 + \theta_2 f_2 + \theta_3 f_3$ >= 0
      - -0.5 + 1 + 0 + 0 = 0.5
        - 0.5 is greater than 1
 - If we had **another point** far away from all three

    - This equates to -0.5
      - So we predict 0
  - Considering our parameter, for points near l^1 and l^2 you predict 1, but for points near l^3 you predict 0
  - Which means we create a non-linear decision boundary that goes a lil' something like this;
    - Inside we predict y = 1
    - Outside we predict y = 0
- So this show how we can create a non-linear boundary with landmarks and the kernel function in the support vector machine
  - But
    - How do we get/chose the landmarks
    - What other kernels can we use (other than the Gaussian kernel)

<u>Kernels II</u>

- Filling in missing detail and practical implications regarding kernels
- Spoke about picking landmarks manually, defining the kernel, and building a hypothesis function
  - Where do we get the landmarks from?
  - For complex problems we probably want lots of them

Choosing the landmarks

- Take the training data
- For each example place a landmark at exactly the same location
- So end up with m landmarks
  - One landmark per location per training example
  - Means our features measure how close to a training set example something is
- Given a new example, compute all the f values
  - Gives you a feature vector f (f_0 to f_m)
    - f_0 = 1 always
- A more detailed look at generating the f vector
  - If we had a training example - features we compute would be using (x^i, y^i)
    - So we just cycle through each landmark, calculating how close to that landmark actually x^i is
      - $f_1^i, = k(x^i, l^1)$
      - $f_2^i, = k(x^i, l^2)$
      - ...
      - $f_m^i, = k(x^i, l^m)$
    - Somewhere in the list we compare x to itself... (i.e. when we're at f_i^i)
      - So because we're using the Gaussian Kernel this evalues to 1
    - Take these m features ($f_1, f_2 ... f_m$) group them into an [m +1 x 1] dimensional vector called f
      - f^i is the f feature vector for the ith example
      - And add a 0th term = 1
- Given these kernels, how do we use a support vector machine

SVM hypothesis prediction with kernels

- Predict y = 1 if ($\theta^T f$) >= 0
  - Because θ = [m+1 x 1]
  - And f = [m +1 x 1]
- So, this is how you make a prediction assuming you already have θ
  - How do you get θ?

SVM training with kernels

- Use the SVM learning algorithm

$$\min_{\theta} C \sum_{i=1}^{m} y^{(i)} cost_1(\theta^T f^{(i)}) + (1 - y^{(i)})cost_0(\theta^T f^{(i)}) + \frac{1}{2} \sum_{j=1}^{n} \theta_j^2$$

  - Now, we minimize using f as the feature vector instead of x
  - By solving this minimization problem you get the parameters for your SVM
- In this setup, m = n
  - Because number of features is the number of training data examples we have
- One final mathematic detail (not crucial to understand)
  - If we ignore θ_0 then the following is true

$$\sum_{j=1}^{n} \theta_j^2 = \theta^T \theta$$

- ○ What many implementations do is
  $$\theta^T \mathbf{M} \theta$$
    - ▪ Where the matrix M depends on the kernel you use
    - ▪ Gives a slightly different minimization - means we determine a rescaled version of θ
    - ▪ Allows more efficient computation, and scale to much bigger training sets
    - ▪ If you have a training set with 10 000 values, means you get 10 000 features
      - ▪ Solving for all these parameters can become expensive
      - ▪ So by adding this in we avoid a for loop and use a matrix multiplication algorithm instead
- You can apply kernels to other algorithms
  - ○ But they tend to be very computationally expensive
  - ○ But the SVM is far more efficient - so more practical
- Lots of good off the shelf software to minimize this function

- **SVM parameters (C)**
  - ○ Bias and variance trade off
  - ○ Must chose C
    - ▪ C plays a role similar to 1/LAMBDA (where LAMBDA is the regularization parameter)
  - ○ Large C gives a hypothesis of **low bias high variance** --> overfitting
  - ○ Small C gives a hypothesis of **high bias low variance** --> underfitting
- **SVM parameters (σ^2)**
  - ○ Parameter for calculating f values
    - ▪ Large σ^2 - f features vary more smoothly - higher bias, lower variance
    - ▪ Small σ^2 - f features vary abruptly - low bias, high variance

SVM - implementation and use

- So far spoken about SVM in a very abstract manner
- What do you need to do this
  - ○ Use SVM software packages (e.g. liblinear, libsvm) to solve parameters θ
  - ○ Need to specify
    - ▪ Choice of parameter C
    - ▪ Choice of kernel

Choosing a kernel

- We've looked at the **Gaussian kernel**
  - ○ Need to define σ (σ^2)
    - ▪ Discussed σ^2
  - ○ When would you chose a Gaussian?
    - ▪ If n is small and/or m is large
      - ▪ e.g. 2D training set that's large
  - ○ If you're using a Gaussian kernel then you may need to implement the kernel function
    - ▪ e.g. a function
      fi = kernel(x1,x2)
      - ▪ Returns a real number
    - ▪ Some SVM packages will expect you to define kernel
    - ▪ Although, some SVM implementations include the Gaussian and a few others
      - ▪ Gaussian is probably most popular kernel
  - ○ NB - make sure you perform **feature scaling** before using a Gaussian kernel
    - ▪ If you don't features with a large value will dominate the f value
- Could use no kernel - **linear kernel**
  - ○ Predict y = 1 if (θ^T x) >= 0
    - ▪ So no f vector

- - - Get a standard linear classifier
  - ○ Why do this?
    - If n is large and m is small then
      - Lots of features, few examples
      - Not enough data - risk overfitting in a high dimensional feature-space
- Other choice of kernel
  - ○ Linear and Gaussian are most common
  - ○ Not all similarity functions you develop are valid kernels
    - Must satisfy **Merecer's Theorem**
    - SVM use numerical optimization tricks
      - Mean certain optimizations can be made, but they must follow the theorem
  - ○ **Polynomial Kernel**
    - We measure the similarity of x and l by doing one of
      - $(x^T l)^2$
      - $(x^T l)^3$
      - $(x^T l+1)^3$
    - General form is
      - $(x^T l+Con)^D$
    - If they're similar then the inner product tends to be large
    - Not used that often
    - Two parameters
      - Degree of polynomial (D)
      - Number you add to l (Con)
    - Usually performs worse than the Gaussian kernel
    - Used when x and l are both non-negative
  - ○ **String kernel**
    - Used if input is text strings
    - Use for text classification
  - ○ **Chi-squared kernel**
  - ○ **Histogram intersection kernel**

Multi-class classification for SVM

- Many packages have built in multi-class classification packages
- Otherwise use one-vs all method
- Not a big issue

Logistic regression vs. SVM

- When should you use SVM and when is logistic regression more applicable
- If n (features) is large vs. m (training set)
  - ○ e.g. text classification problem
    - Feature vector dimension is 10 000
    - Training set is 10 - 1000
    - Then use logistic regression or SVM with a linear kernel
- If n is small and m is intermediate
  - ○ n = 1 - 1000
  - ○ m = 10 - 10 000
  - ○ Gaussian kernel is good
- If n is small and m is large
  - ○ n = 1 - 1000
  - ○ m = 50 000+
    - SVM will be slow to run with Gaussian kernel
  - ○ In that case
    - Manually create or add more features
    - Use logistic regression of SVM with a linear kernel
- Logistic regression and SVM with a linear kernel are pretty similar
  - ○ Do similar things

- - Get similar performance
- A lot of SVM's power is using diferent kernels to learn complex non-linear functions
- For all these regimes a well designed NN should work
  - But, for some of these problems a NN might be slower - SVM well implemented would be faster
- SVM has a convex optimization problem - so you get a global minimum
- It's not always clear how to chose an algorithm
  - Often more important to get enough data
  - Designing new features
  - Debugging the algorithm
- SVM is widely perceived a very powerful learning algorithm
